

This project's simulation
(literal paper flux value, peak density 0.0499)

Note: this run uses the flux value from the paper's own Table 1, translated into this project's units. Peak bacterial density stays at essentially the seed's starting value (~ 0.05) across all 50 time steps -- i.e. negligible growth in this timeframe at the literal parameter value. This is an honest, unresolved scale-mismatch finding (see project notes), not a solver defect -- the same equations produce correct, sensible growth once given a stronger flux (see the companion 10x comparison).
